# Abstract

In this paper we discuss farthest-point problems in which a set or sequence *S* of *n* points in the plane is given in advance and can be preprocessed to answer various queries efficiently. First, we give a data structure that can be used to compute the point farthest from a query line segment in  $O(\log^2 n)$  time. Our data structure needs  $O(n \log n)$  space and preprocessing time. To the best of our knowledge no solution to this problem has been suggested yet. Second, we show how to use this data structure to obtain an output-sensitive query-based algorithm for polygonal path simplification. Both results are based on a series of data structures for fundamental farthest-point queries that can be reduced to each other.

Keywords: Farthest-point queries; Line-segment queries; Polygonal path simplification

# 1. Introduction

Proximity problems are fundamental in computational geometry and have been studied intensively since Knuth [17] posed the post-office problem about three decades ago. In this paper we discuss farthest-point problems in which a set or sequence S of n points in the plane is given in advance and can be preprocessed to answer various queries efficiently. Our main results are the following.

First, we present a data structure that can be used to compute the point farthest from a query line segment in  $O(\log^2 n)$  time. Our data structure needs  $O(n \log n)$  space and preprocessing time. To the best of our knowledge no

solution to this problem has been suggested yet. Second, we design a data structure that can be used to simplify polygonal paths in the following sense: given a path  $P = (p_1, ..., p_n)$  and a real  $\Delta > 0$  we want to find a subpath P' of P that goes from  $p_1$  to  $p_n$  and consists exclusively of  $\Delta$ -approximating segments according to the tolerance-zone criterion, i.e., a sequence of line segments  $\overline{p_i p_k}$  with the property that each  $p_j$  with i < j < k is at most  $\Delta$  away from  $\overline{p_i p_k}$ . We are interested in a min-# subpath, i.e., a subpath with the minimum number of vertices. This is motivated by data reduction (e.g. in geographic information systems) and considered an important problem—finding a near-linear solution is listed as problem 24 in the *Open Problems Project* [21]. Our query-based algorithm finds a min-# subpath in  $O(n^2 \log^3 n)$  worst-case running time. This is slightly worse than the quadratic running time of the best incremental algorithm [8], but much better in practice since, as we will see later, the running time of our algorithm is output sensitive. Our algorithm has the same structure as a query-based algorithm [13] for the weaker *infinite-beam criterion* which requires that a vertex  $p_j$  of P that is shortcut by an edge  $\overline{p_i p_k}$  of P' must be within distance  $\Delta$  from the *line* through  $p_i$  and  $p_k$ . The algorithm [13] outperformed an incremental algorithm similar to [8] in an experimental evaluation.

Before we go into more detail, we briefly introduce some notations. In this paper |pq| denotes the length of the line segment  $\overline{pq}$ , i.e., the Euclidean distance of p and q. For  $p \neq q$  we use pq to denote the line through p and q, directed from p to q. By projection we will always mean orthogonal projection.

Both main results of this paper rely on our solution of the following problem:

## FARTHESTVERTEXINHALFPLANE (FV-halfplane):

2

Preprocess a convex *n*-gon *C* for queries of the following type. Given  $(q, l_q)$ , where *q* is a point and  $l_q$  is a directed line through *q*, decide whether there is a vertex of *C* to the left of  $l_q$ . If yes, report the one farthest from *q*. (See Fig. 1.)

Other than one might think at first glance, this problem cannot be solved simply by binary search on the vertices of *C* since the distance from the query point *q* is not unimodal on the boundary of *C*. Our data structure for FV-halfplane answers queries in  $O(\log^2 n)$  time given  $O(n \log n)$  space and preprocessing time.

Next we address a problem whose solution yields our first main result, an efficient data structure for finding points farthest from query line segments.

# FARTHESTPOINTINHALFSTRIP (FP-halfstrip):

Preprocess a set *S* of *n* points for queries of the following type. Given a triplet  $(q, l_q, \Delta)$ , where *q* is a point and  $l_q$  is a directed line through *q* such that all points in *S* are within distance  $\Delta$  from  $l_q$ , decide whether there is a point  $p \in S$  such that (i)  $|qp| \ge \Delta$ , and (ii) the projection of *p* on  $l_q$  lies before *q*. If yes, report the point farthest from *q* that fulfills conditions (i) and (ii). (See Fig. 2.)

We prove that if there are points fulfilling conditions (i) and (ii), then among these the one farthest from q among them lies on the convex hull of S. Note that this statement does not hold if we drop condition (i): in Fig. 3 the point p is farthest from q among all points in S that fulfill condition (ii), but p does not lie on the convex hull of S. Thanks to condition (i), our data structure for FV-halfplane in fact solves FP-halfstrip within the same asymptotic bounds. This in turn yields our first main result: we can preprocess a set S of n points in  $O(n \log n)$  time and space such that the point in S farthest from a query line segment s can be reported in  $O(\log^2 n)$  time.

For our second main result, which deals with polygonal path simplification, point order is important. Thus we consider an indexed version of FP-halfstrip:

# FARTHESTINDEXEDPOINTINHALFSTRIP (FIP-halfstrip):

Preprocess a sequence  $S = (p_1, ..., p_n)$  of points for queries of the following type. Given a triplet  $(i, j, \Delta)$  such that all points  $p_k$  with i < k < j are within distance  $\Delta$  from the line  $p_i p_j$ , decide whether there is a point  $p_k$  with i < k < j such that (i)  $|p_i p_k| \ge \Delta$ , and (ii) the projection of  $p_k$  on  $p_i p_j$  lies before  $p_i$ . If yes, report the point  $p_k$  farthest from  $p_i$  that fulfills (i) and (ii). (See Fig. 4.)

Our time and space bounds for FIP-halfstrip are a log-factor above those for FV-halfplane. The data structure for FIP-halfstrip yields an output-sensitive query-based algorithm for polygonal path simplification. Given a polygonal path  $P = (p_1, \ldots, p_n)$  in  $\mathbb{R}^2$  and a real  $\Delta > 0$ , the algorithm computes a subpath of P with the minimum number  $m_{tz}$  of vertices among all subpaths satisfying the tolerance-zone criterion. The algorithm runs in  $O(F_{tz}(m_{tz}) n \log^3 n)$  time and uses  $O(n \log^2 n)$  space, where  $F_{tz}(m_{tz}) \leq n$  is the number of vertices that can be reached from  $p_1$  with at most  $(m_{tz} - 2) \Delta$ -approximating segments.

Next we look at a batched version of an indexed farthest-point problem. Given a sequence S of points, we want to observe how the point farthest from a fixed point p changes over time while we insert the points of S one after the other. In each round we ignore all those points that lie in a halfplane determined by the newly inserted point. Our solution assumes knowledge of S before the observation starts.

# BATCHEDFARTHESTINDEXEDPOINTINHALFPLANE (BFIP-halfplane):

Given a sequence  $S = (p_1, ..., p_n)$  of points and a point  $p \notin S$ , decide for each  $i \in \{1, ..., n\}$  whether there is a point  $p_f \in \{p_1, ..., p_i\}$  that lies on the same side as p with respect to the perpendicular bisector of p and  $p_i$ . If yes, report the point  $p_f$  farthest from p that has the above property.

Our algorithm for this problem takes  $O(n \log^2 n)$  time and  $O(n \log n)$  space.

Our paper is structured as follows. In Section 2 we briefly review related work. In Section 3 we first consider the problem FP-halfplane, a generalization of FV-halfplane where points do not have to be in convex position. In Section 4 we solve the convex case, i.e., FV-halfplane. In Section 5 we show that FP-halfstrip can be reduced to FV-halfplane and how this helps to solve the farthest-point-to-line-segment problem. In Section 6 we show how the data structure for FV-halfplane can be used to solve the indexed problem FIP-halfstrip. Section 7 settles the connection between FIP-halfstrip and polygonal path simplification. In Section 8 we address the batched problem BFIP-halfplane. In Section 9 we conclude.

# 2. Previous work

The problems that we study are related to the nearest-point query problem [12,18,20,22] and to the all-pairs farthestand closest-neighbors problem [2,3,24]. Cole and Yap [12] consider closest-point-to-line queries and present a data structure with  $O(\log n)$  query time that needs  $O(n^2)$  preprocessing time and space. The same result is obtained by Lee and Ching [18] using a duality-based approach. A data structure with  $O(n^{0.695})$  query time that needs  $O(n \log n)$ preprocessing time and O(n) space is presented by Mitra and Chaudhuri [20]. Using simplicial partitions, Mukhopadhyay [22] constructs in  $O(n^{1+\varepsilon})$  time a data structure of size  $O(n \log n)$  that finds a point *closest* to a query line in  $O(n^{\frac{1}{2}+\varepsilon})$  time for arbitrary  $\varepsilon > 0$ . Finding a point *farthest* from a query line seems to be easier: it can be done by  $O(\log n)$  time given  $O(n \log n)$  preprocessing and O(n) space, see Section 5. This data structure helps us to show how to find a point farthest from a query line segment in  $O(\log^2 n)$  time given  $O(n \log n)$  preprocessing and space. Bespamyatnikh and Snoeyink [6] show how to preprocess a set *S* of *n* points in  $O(\log n)$  time using O(n) space such that the point closest to a query line segment *outside* the convex hull of *S* can be reported in  $O(\log n)$  time. Using this data structure, Bespamyatnikh [5] shows how to solve in  $O(n \log^2 n)$  time a batched problem where *n* points and *n disjoint* line segments are given and for each segment the *closest* point has to be determined. In contrast, our data structure for FP-halfstrip (see Section 5) answers *farthest*-point queries for an *arbitrary* line segment in  $O(\log^2 n)$ time each, given  $O(n \log n)$  space and preprocessing time.

While the all-pairs nearest neighbors of n points in a fixed dimension can be computed in optimal  $O(n \log n)$  time [24], no algorithm is known to compute the all-pairs farthest neighbors of n points within the same time bound.

Agarwal et al. [3] show that the all-pairs farthest neighbors in  $\mathbb{R}^3$  can be computed in  $O(n^{4/3} \log^{4/3} n)$  time. If the points are the vertices of a convex polygon in  $\mathbb{R}^2$ , the all-pairs farthest neighbors can be computed in linear time, even though the problem has a complexity of  $\Omega(n \log n)$  for arbitrary points [2]. In  $\mathbb{R}^3$  the convex case can be solved in  $O(n \log^2 n)$  expected time [11].

Although the closest-point-to-line query problem and the all-pairs farthest neighbors problem are well understood, we are not aware of any published work on the farthest-point problems we consider.

### 3. Farthest point in halfplane

4

In this section, for completeness we address the following natural generalization of FV-halfplane.

FARTHESTPOINTINHALFPLANE (FP-halfplane):

Preprocess a set S of n points for queries of the following type. Given  $(q, l_q)$ , where q is a point and  $l_q$  is a directed line through q, decide whether there is a point in S to the left of  $l_q$ . If yes, report the one farthest from q.

We use the following structure: a *simplicial partition* for a set *S* of *n* points in the plane is a collection of pairs  $\Psi(S) = \{(S_1, t_1), (S_2, t_2), \dots, (S_r, t_r)\}$ , where the sets of type  $S_i$  partition *S*, and  $t_i$  is a triangle that contains  $S_i$  for  $i = 1, \dots, r$ . An example of a point set *S* and a simplicial partition of *S* of size 4 are given in Fig. 5. For a given simplicial partition  $\Psi(S)$ , the *crossing number* of a line *l* is the number of triangles of  $\Psi(S)$  that *l* intersects. For example, the line *l* in Fig. 5 has crossing number 3. The crossing number of  $\Psi(S)$  is the maximum crossing number over all possible lines *l*. We say that a simplicial partition  $\Psi(S)$  is *fine* if  $|S_i| \leq 2n/r$ , for every  $1 \leq i \leq r$ . Matoušek [19] showed the following important result on the construction of fine simplicial partitions with low crossing number:

**Theorem 1** [19]. Let *S* be a set of *n* points in the plane, and let *r* be an integer with  $1 \le r \le n/2$ . Then a fine simplicial partition  $\Psi(S)$  of size *r* with crossing number  $O(\sqrt{r})$  exists. If *r* is constant,  $\Psi(S)$  can be constructed in O(n) time and space.

Simplicial partitions are the basis of an efficient search data structure, called *partition tree*. The root of a partition tree of *S* has *r* children  $v_1, \ldots, v_r$  that correspond one-to-one to the sets  $S_i$  in  $\Psi(S)$ . Each child  $v_i$  is the root of a recursively defined partition tree of  $S_i$ . The partition tree of *n* points can be computed in  $O(n \log n)$  time and uses O(n) space [19].

To solve the problem FP-halfplane we will take advantage of the *farthest-point Voronoi diagram*. Given a set of n sites in the plane, the farthest-point Voronoi diagram is a partition of the plane into cells, each of which is associated with a site and contains all the points in the plane that are *farther* from that site than from any other site. Unlike the *nearest-point* Voronoi diagram, in the farthest-point Voronoi diagram only the sites on the convex hull have a non-empty Voronoi region associated with them. In the plane, the farthest-point Voronoi diagram can be constructed in  $O(n \log n)$  time if the sites are in general position [23]. When the sites are the vertices of a convex polygon, the diagram can be constructed [1] and preprocessed for planar point-location queries [14] in linear time.

We start by constructing the partition tree of *S*. Recall that for a node  $v_i$  of the tree,  $S_i$  is the subset of *S* stored at  $v_i$ , and  $t_i$  is the triangle of  $\Psi(S)$  that contains  $S_i$ . Let  $n_i = |S_i|$ . For each node  $v_i$  we compute and store the farthestpoint Voronoi diagram of  $S_i$  and preprocess it for planar point-location queries. This takes  $\tau(n_i) = O(n_i \log n_i)$  time and uses  $\sigma(n_i) = O(n_i)$  space. Let T(n) and S(n) be the total construction time and space consumption of these

Fig. 5. An example of a simplicial partition of size 4. The points in S<sub>1</sub>, S<sub>2</sub>, S<sub>3</sub>, and S<sub>4</sub> are marked by boxes, circles, disks, and squares, respectively.

 $O. \ Daescu \ et \ al. \ / \ Computational \ Geometry \ \bullet \bullet \ (\bullet \bullet \bullet \bullet) \ \bullet \bullet - \bullet \bullet \bullet$ 

5

secondary data structures, respectively. They satisfy the following recurrences:  $T(n) \leq \tau(n) + \sum_{i=1}^{r} T(n_i)$  and  $S(n) = \sigma(n) + r + \sum_{i=1}^{r} S(n_i)$  for n > 1, and T(1) = S(1) = 1. Since we have that  $\sum_{i=1}^{r} n_i = n$ , that  $n_i \leq 2n/r$ , and that r is a constant, the general version of the Master theorem [10] yields that  $T(n) = O(n \log^2 n)$ . Thus T(n) dominates the preprocessing time. Similar arguments as for T(n) show that  $S(n) = O(n \log n)$ . Thus S(n) dominates the space consumption.

When we query the partition tree, we want to find the point in *S* farthest from the query point *q* that is left of the directed line  $l_q$ . We have to consider two different kinds of point sets  $S_i$ . First we consider the  $O(\sqrt{r})$  point sets  $S_i$  with  $t_i \cap l_q \neq \emptyset$ . For each such point set  $S_i$ , we recursively search in its simplicial partition  $\Psi(S_i)$ . Second we have to consider those point sets  $S_i$  that lie left of the line  $l_q$ . For each of these at most  $r - O(\sqrt{r})$  point sets, we locate the query point *q* in the farthest-point Voronoi diagram to find the point farthest from *q*. Point location takes time logarithmic in the size of the partition. Therefore, we get the following recurrence for the query time: Q(1) = 1 and for n > 1

$$Q(n) \leqslant r + \sum_{t_i \cap l_q = \emptyset} \mathcal{O}(\log n_i) + \sum_{t_i \cap l_q \neq \emptyset} Q(n_i).$$
<sup>(1)</sup>

Let  $c\sqrt{r} = O(\sqrt{r})$  be the crossing number of  $\Psi(S)$ . Given an arbitrary  $\varepsilon > 0$ , we can set  $r = \lceil 2(c\sqrt{2})^{1/\varepsilon} \rceil$ , which makes r a constant and yields  $Q(n) = O(n^{1/2+\varepsilon})$  for n large enough, i.e.,  $n \ge 2r$ . This can be seen by bounding the first sum in inequality (1) by  $O(r \log n)$  and the second sum by  $c\sqrt{r} \cdot Q(2n/r)$ . We sum up:

**Theorem 2.** There is a data structure for FP-halfplane that answers queries in  $O(n^{1/2+\varepsilon})$  time given  $O(n \log^2 n)$  preprocessing time and  $O(n \log n)$  space.

#### 4. Farthest vertex in halfplane

We now tackle FV-halfplane, the convex case of FP-halfplane. It is the basis of our solutions for the problems FP-halfstrip and FIP-halfstrip. The problem is to preprocess a convex *n*-gon *C* such that for a query pair  $(q, l_q)$ , where *q* is a point and  $l_q$  is a directed line through *q*, one can efficiently decide whether there is a vertex of *C* left of  $l_q$  and if yes, report the one farthest from *q*.

Given a query pair  $(q, l_q)$ , we first compute potential intersection points of  $l_q$  with the boundary  $\partial C$  of C. This can be done by binary search in  $O(\log n)$  time since the distance from  $l_q$  is a unimodal function on  $\partial C$ . There are three possible cases, see Fig. 6: (a)  $l_q \cap C = \emptyset$  and C lies to the right of  $l_q$ ; (b)  $l_q \cap C = \emptyset$  and C lies to the left of  $l_q$ ; (c)  $l_q$  has nonempty intersection with C. Knowing that  $l_q \cap C = \emptyset$ , case (a) can be handled in constant time. Case (b) reduces to finding the point on C farthest from  $l_q$ . This can be achieved in  $O(\log n)$  time by locating the query point in the farthest-point Voronoi diagram of the vertices of C. In the remainder of this section we show how to handle case (c).

In the preprocessing phase, we construct a balanced binary tree T in  $O(n \log n)$  time as follows. The vertices of the convex polygon C, in counter-clockwise order from the rightmost vertex, are associated with the leaves of T. At each internal node u, we compute and store the farthest-point Voronoi diagram  $V_u$  of the leaf descendants of u. This takes linear time for each level of T since all point sets are in convex position [1]. Within the same asymptotic time bound we then preprocess  $V_u$  for planar point-location queries [14]. Thus the computation of T takes  $O(n \log n)$  time in total.

Fig. 6. The three possible cases for the intersection of  $l_q$  with C.

We query T as follows. Consider the edges of C intersected by  $l_q$ . If these edges are incident to the same vertex v of C to the left of  $l_q$  then we report v. Otherwise the edges have two different endpoints to the left of  $l_q$ . Let s be the first and t the second endpoint in counter-clockwise order on C, see Fig. 6. We assume that the sequence of points on C that lie to the left of  $l_q$  does not contain both the rightmost vertex and its counter-clockwise predecessor. Otherwise the words left and right in the following description have to be exchanged.

We walk in *T* from *s* to *t* and collect a set  $\mathcal{V}$  of  $O(\log n)$  farthest-point Voronoi diagrams in two phases. In the ascending phase we go upwards from *s* until we reach the least common ancestor *a* of *s* and *t*. Whenever we get to a node  $u \neq a$  from its *left* child, we add to  $\mathcal{V}$  the Voronoi diagram stored at the right child of *u*. In the descending phase we go down from *a* towards *t*. Whenever we go to the *right* child of a node  $u \neq a$ , we add to  $\mathcal{V}$  the Voronoi diagram stored at the left child of *u*. In the descending phase stored at the left child of *u*. Clearly, all points associated with these Voronoi diagrams are to the left of  $l_q$  and thus the sought vertex is either *s*, *t* or one of these points. We locate *q* in  $O(\log n)$  time in each farthest-point Voronoi diagram in  $\mathcal{V}$  and keep track of the point farthest from *q*. This answers a query in  $O(\log^2 n)$  time.

**Theorem 3.** There is a data structure for FV-halfplane that answers queries in  $O(\log^2 n)$  time given  $O(n \log n)$  space and preprocessing time.

# 5. Farthest point in halfstrip

6

In this section we want to preprocess a set *S* of *n* points for queries of the following type. Given a triplet  $(q, l_q, \Delta)$ , where *q* is a point and  $l_q$  is a directed line through *q* such that all points in *S* are within distance  $\Delta$  from  $l_q$ , decide whether there is a point  $p \in S$  such that (i)  $|qp| \ge \Delta$ , and (ii) the projection of *p* on  $l_q$  lies before *q*. If yes, report the point farthest from *q* that fulfills (i) and (ii). (See Fig. 2.)

FP-halfstrip can be solved by the same approach as for FP-halfplane: construct a partition tree based on a fine simplicial partition in  $O(n^{1+\varepsilon})$  time [19] and enhance it with a second-level data structure. For the points at each internal node of the partition tree, the second-level structure consists of the farthest-point Voronoi diagram preprocessed for planar point location.

We would prefer to use the faster solution for FV-halfplane, i.e., for the convex case. At first glance it seems that this is not possible, since among the points that fulfill condition (ii), the point p farthest from the query point q may lie *inside* the convex hull C of S, see Fig. 3. Condition (i), however, does in fact give us a way to use the data structure for FV-halfplane to solve FP-halfstrip.

For a point q and a directed line  $l_q$  with  $q \in l_q$  let  $l'_q$  be the directed line that results from turning  $l_q$  around q by +90°. Then the points whose projection on  $l_q$  lies before q are exactly the points to the left of  $l'_q$ .

**Lemma 4.** Given a set  $S \subset \mathbb{R}^2$  and a triplet  $(q, l_q, \Delta)$ , where q is a point and  $l_q$  is a directed line through q such that all points in S are within distance  $\Delta$  from  $l_q$ , if there is a point  $p \in S$  such that (i)  $|qp| \ge \Delta$ , and (ii) p lies to the left of  $l'_q$ , then among all points in S to the left of  $l'_q$  the point farthest from q is a vertex of the convex hull C of S.

**Proof.** Let  $\Sigma$  be the closed strip that is bounded by the two lines at distance  $\Delta$  from  $l_q$  and let H be the part of S to the right of  $l'_q$ . In Fig. 7,  $\Sigma$  is the whole shaded area, H is the darker part. Let p be the point farthest from q to the left of  $l'_q$ , let D be a disk centered at q that touches p, and let  $D' = D \cap \Sigma$ . In Fig. 7, the boundary of D is dotted, that of D' is bold solid. Finally let  $U = D' \cup H$ . Then p lies on the boundary of U. If  $|pq| \ge \Delta$ , U is convex. Thus for any (finite) set F with  $p \in F \subset U$  it holds that p is a vertex of the convex hull of F.  $\Box$ 

Fig. 7. The point p farthest from q is a vertex of the convex hull C of S if  $|qp| \ge \Delta$ .

By Lemma 4 we can now reduce FP-halfstrip to FV-halfplane.

**Theorem 5.** There is a data structure for FP-halfstrip that answers queries in  $O(\log^2 n)$  time given  $O(n \log n)$  space and preprocessing time.

**Proof.** From Lemma 4, it follows that it suffices to consider the vertices of the convex hull of *S*. Thus, we first compute the convex hull *C* of the *n* points in  $O(n \log n)$  time [23]. We then proceed as for FV-halfplane, see Section 4.  $\Box$ 

This yields our first main result, a data structure for finding the point farthest from a query segment.

**Theorem 6.** Given a set S of n points, we can construct in  $O(n \log n)$  space and preprocessing time a data structure that for any line segment s determines in  $O(\log^2 n)$  time the point in S farthest from s.

**Proof.** Let s = uv and let  $\ell = uv$  be the line that is directed from u to v. There are two mutually exclusive cases. In the first case the point farthest from s is also the point farthest from  $\ell$ . For this case we preprocess S by computing in  $O(n \log n)$  time the convex hull C of S. Then this case can be solved by binary search in  $O(\log n)$  time since the distance from  $\ell$  is unimodal on C.

Note that the point farthest from  $\ell$  also gives us the smallest value  $\Delta$  such that *S* lies within a  $\Delta$ -strip around  $\ell$ . For the second case, let  $S_w$  ( $w \in \{u, v\}$ ) be the set of all points in *S* that are separated from *s* by the line orthogonal to *s* in *w*. In this case the point farthest from *s* is the point in  $S_u$  farthest from *u* or the point in  $S_v$  farthest from *v*. These two points can be determined within the desired time and space bounds by querying a data structure for FP-halfstrip with the triplets ( $u, uv, \Delta$ ) and ( $v, vu, \Delta$ ).  $\Box$ 

# 6. Farthest indexed point in halfstrip

We solve FIP-halfstrip, the indexed version of FP-halfstrip, in a way similar to FV-halfplane. At the same time we use the data structure for FV-halfplane as a plug-in. Let the points in the input sequence *S* be denoted by  $p_1, \ldots, p_n$ . In the preprocessing phase we construct a balanced binary tree T of the same structure as for FV-halfplane. The *i*th leaf of T is associated with the point  $p_i \in S$ . We build the tree T bottom-up. At each internal node v, we compute and store the convex hull  $C_v$  of the leaf descendants  $p_{i(v)}, \ldots, p_{j(v)}$  of v. We also compute and store at v a secondary level data structure, namely the tree described in Section 4 that solves FV-halfplane (i.e., FP-halfstrip) for the vertices of  $C_v$ . The overall computation of T requires  $O(n \log^2 n)$  time and space.

A query is also very similar to FV-halfplane: for a query  $(i, j, \Delta)$ , we follow the unique path from  $p_i$  to  $p_j$  in  $\mathcal{T}$  collecting a set  $\mathcal{C}$  of  $O(\log n)$  convex hulls whose union contains all points  $p_k$  with i < k < j. This is done in the same way as with the set of farthest-point Voronoi diagrams in Section 4. For each convex hull  $C_v \in \mathcal{C}$ , we solve FP-halfstrip for the triplet  $(p_i, p_i p_j, \Delta)$  using the secondary data structure stored at vertex v of  $\mathcal{T}$ . (Compare the situations in Figs. 2 and 4!) Thus we can decide in  $O(\log^2 |C_v|)$  time whether there is a  $k, i(v) \leq k \leq j(v)$ , such that the point  $p_k$  satisfies the two FIP-halfstrip conditions. Since the size of the set  $\mathcal{C}$  is  $O(\log n)$ , the overall query time is  $O(\log^3 n)$ .

**Theorem 7.** There is a data structure for FIP-halfstrip that answers queries in  $O(\log^3 n)$  time given  $O(n \log^2 n)$  space and preprocessing time.

# 7. Polygonal path simplification and FIP-halfstrip

In this section we use our solution of FIP-halfstrip to extend a recent result of Daescu and Mi [13] for the min-# version of the polygonal path simplification problem: Given a polygonal path  $P = (p_1, p_2, ..., p_n)$ , with *n* vertices, and an error tolerance  $\Delta$ , find a subpath  $P' = (p_{i_1} = p_1, p_{i_2}, ..., p_{i_m} = p_n)$  of *P* such that the vertices of *P'* are an ordered subset of the vertices of *P*, each line segment  $\overline{p_{i_j}p_{i_{j+1}}}$  of *P'* is a  $\Delta$ -approximation of the corresponding subpath  $(p_{i_j}, p_{i_j+1}, ..., p_{i_{j+1}})$  of *P*, and the number of vertices *m* of *P'* is minimized.

To decide whether a line segment of P' is a  $\Delta$ -approximation of the corresponding subpath of P, two error criteria are commonly used: the *tolerance-zone* criterion and the *infinite-beam* criterion. The first criterion produces a

8

compressed version that better captures the features of the original path, while the second gives a better degree of compression. According to the tolerance-zone criterion, all vertices of the approximated subpath of P must be within distance  $\Delta$  from the approximating line segment of P', while according to the infinite-beam criterion all vertices of the approximated subpath must be within distance  $\Delta$  from the line supporting the approximating line segment.

Earlier algorithms for the min-# problem first compute the  $\Delta$ -approximation graph  $G_{\Delta}$  with vertex set  $\{p_1, \ldots, p_n\}$ and an edge for each  $\Delta$ -approximating segment. Then breadth-first search in  $G_{\Delta}$  yields a min-# path from  $p_1$  to  $p_n$ . Chin and Chan [7] showed how to compute  $G_{\Delta}$ —and thus solve the min-# problem—in  $O(n^2)$  time and space. Chen and Daescu [8] managed to avoid the explicit computation of  $G_{\Delta}$  by combining the computation of the  $\Delta$ approximating segments and the breadth-first search. This was achieved by an iterative procedure that for each  $p_i$ incrementally determined the largest j such that  $\overline{p_i p_j}$  is a  $\Delta$ -approximating segment. This iterative-incremental algorithm needs only linear space. Its running time is  $O(n^2)$  for the tolerance-zone criterion and  $O(n^2 \log n)$  for the infinite-beam criterion.

For a different metric, namely the  $L_1$ -metric, a subquadratic-time algorithm for the min-# problem has been proposed by Agarwal and Varadarajan [4]. Their algorithm is based on the divide-and-conquer technique, sophisticated data structures and a compact representation of  $G_{\Delta}$ . Time and space complexity of their algorithm are  $O(n^{4/3+\varepsilon})$ , where  $\varepsilon > 0$  can be chosen arbitrarily small. However, the algorithm cannot be extended to the case of the Euclidean metric.

Daescu and Mi [13] presented an output-sensitive query-based algorithm for the infinite-beam criterion. The algorithm runs in  $O(F_{ib}(m_{ib}) n \log n)$  time, where  $F_{ib}(m_{ib}) \leq n$  is the number of vertices that can be reached from  $p_1$  with at most  $(m_{ib} - 2) \Delta$ -approximating segments according to the infinite-beam criterion, and  $m_{ib}$  is the number of vertices on an optimal approximating path, again according to the infinite-beam criterion. While the asymptotic running time of this algorithm is the same as that of the algorithm by Chen and Daescu [8], experiments showed that for random paths the value of  $F_{ib}(m_{ib})$  is usually significantly smaller than the number *n* of vertices on the input path [13].

We repeat the description of this algorithm here since only a slight modification is necessary to apply it to the tolerance-zone criterion. The general structure of the algorithm is outlined in Algorithm 1. In the pseudo-code  $d(p, \ell)$  denotes the Euclidean distance of a point p from a line  $\ell$ .

Algorithm 1 computes an array *s* of integers where for j = 1, ..., n the value s[j] is the number of vertices in an optimal solution to the min-# problem on the subpath from  $p_1$  to  $p_j$ . At the start, the algorithm sets s[1] = 0 and  $s[j] = \infty$  for j = 2, ..., n, and places the index 1 into an initially empty queue Q. Then, it repeats the following operations until s[n] is updated for the first time. Let *i* be the first index in Q. The algorithm removes *i* from Q and finds (through the use of a dynamic binary search tree T that contains only unvisited vertices) the first index j > isuch that  $s[j] = \infty$ . Then, for each  $p_{j'}$  with  $j' \ge j$  and  $s[j'] = \infty$ , the algorithm queries a geometric data structure to determine the vertex  $p_k$  with i < k < j' that is farthest from the line  $p_i p_{j'}$ . If  $d(p_k, p_i p_{j'}) \le \Delta$ , the algorithm sets s[j'] = s[i] + 1 and places j' at the tail of Q.

Since a  $\Delta$ -approximation segment according to the tolerance-zone criterion is also a  $\Delta$ -approximation segment according to the infinite-beam criterion, extending Algorithm 1 to the tolerance-zone criterion reduces to answering queries on indexed points, as formulated in problem FIP-halfstrip. More precisely, if the line segment  $\overline{p_{i_j}p_{i_{j+1}}}$  of P', for  $j \in \{1, \ldots, m_{tz} - 1\}$ , approximates the subpath  $P[i_j, i_{j+1}] = (p_{i_j}, p_{i_j+1}, \ldots, p_{i_{j+1}})$  of P according to the infinite-beam criterion, then all the vertices of the subpath  $P[i_j, i_{j+1}] = (p_{i_j}, p_{i_j+1}, \ldots, p_{i_{j+1}})$  of P according to the infinite-beam criterion, then all the vertices of the subpath  $P[i_j, i_{j+1}]$  are within distance  $\Delta$  from the line  $p_{i_j}p_{i_{j+1}}$ . Let  $l_j$  and  $l'_j$  denote the lines orthogonal to  $p_{i_j}p_{i_{j+1}}$  in  $p_{i_j}$  and  $p_{i_{j+1}}$ , respectively. If for each vertex  $p_k$  of P,  $i_j \leq k \leq i_{j+1}$ , with the property that  $l_j$  separates  $p_k$  and  $p_{i_j+1}$  or  $l'_j$  separates  $p_k$  and  $p_{i_j}$ , we have that  $p_k$  is within distance  $\Delta$  from  $p_{i_j}$  or  $p_{i_j p_{i_{j+1}}}$ . Clearly, this reduces to solving FIP-halfstrip, see Section 6. The result is an output sensitive, query-based algorithm for solving the min-# problem under the tolerance-zone criterion.

**Theorem 8.** Given a polygonal path  $P = (p_1, p_2, ..., p_n)$  in the plane, the min-# problem under the tolerance-zone criterion can be solved in  $O(F_{tz}(m_{tz}) n \log^3 n)$  time using  $O(n \log^2 n)$  space, where  $F_{tz}(m_{tz}) \leq n$  is the number of vertices that can be reached from  $p_1$  with at most  $(m_{tz} - 2) \Delta$ -approximating segments, and  $m_{tz}$  is the number of vertices on an optimal approximating path.

Algorithm 1. SIMPLIFYPOLYGONALPATH( $p_1, \ldots, p_n; \Delta$ ).

**Proof.** The algorithm is similar to the query-based algorithm in [13] (here Algorithm 1), except that now each query takes  $O(\log n + \log^3 n)$  time instead of  $O(\log n)$  time: in line 15 we first spend  $O(\log n)$  time to decide whether some segment  $\overline{p_i p_j}$  is a  $\Delta$ -approximating segment according to the infinite-beam criterion. If the answer is positive, we now use Theorem 7 and spend additional  $O(\log^3 n)$  time to decide whether  $\overline{p_i p_j}$  is a  $\Delta$ -approximating segment according to the tolerance-zone criterion. This changes the running time of Algorithm 1 from  $O(F_{ib}(m_{ib}) n \log n)$  to  $O(F_{tz}(m_{tz}) n \log^3 n)$ .  $\Box$ 

# 8. Batched farthest indexed point in halfplane

In this section we consider the problem BFIP-halfplane: given a sequence  $S = (p_1, ..., p_n)$  of points and a point  $p \notin S$ , decide for each  $i \in \{1, ..., n\}$  whether there is a point  $p_f \in \{p_1, ..., p_i\}$  that lies on the same side as p with respect to the perpendicular bisector of p and  $p_i$ . If yes, report the point  $p_f$  farthest from p that has the above property.

A version of BFIP-halfplane without the index restriction has been considered in [16]. There the problem of computing the minimum-sum dipolar spanning tree (MSST) is considered. The MSST of a point set S is a tree with vertex set S and two non-leaf nodes  $x, y \in S$  that minimizes  $|xy| + \max\{r_x, r_y\}$ , where  $r_x$  and  $r_y$  are the radii of two disks centered at x and y whose union covers S. In the computation of the MSST the following subproblem shows up: report for each point  $p_i \in S$  a point farthest from the fixed point  $p \notin S$  that lies on the same side as p with respect to the perpendicular bisector of p and  $p_i$ . In [16] the problem is reduced to the problem of finding for each  $p_i \in S$ the first disk in a sequence of disks that does *not* contain  $p_i$ . This problem has been addressed in [9] under the name *off-line ball exclusion search* (*OLBES*). The authors set up a tree data structure with a space requirement of O(n log n) and then query this structure with each point in S. This results in a total running time of O(n log n) for OLBES in the plane. For dimension d > 2 the problem is solved differently in  $O(n^{2-2/(\lfloor d/2 \rfloor)+1})$  time. In [16], a version of OLBES where all disks intersect a common point is solved in  $O(n \log n)$  time and O(n) space by sweeping an arrangement of circular arcs. The same problem is solved in [15] in  $O(n \log n)$  time and space using a tree data structure and fractional cascading.

We are interested in the problem BFIP-halfplane since it adds a time component to the pure query problem FIP-halfplane. We want to keep track on how the point farthest from the fixed point p changes over time while we insert

the points of S one after the other and ignore all those points that lie in a halfplane determined by the newly inserted point. We solve this problem by setting up a tree data structure similar to that in the proof of Lemma 2 in [15]. Here, however, we must solve a different OLBES problem in each query and thus need to modify our tree successively.

We need some notation. Let D(x, p) be the open disk centered at x that touches p and let h(p,q) be the closed halfplane that contains p and whose boundary is the perpendicular bisector of p and q. Note that  $x \in h(p,q)$  is equivalent to  $|xp| \leq |xq|$ , which in turn is equivalent to  $q \notin D(x, p)$ . This is the basis of the following lemma that we need to prove the correctness of our algorithm for BFIP-halfplane.

**Lemma 9** [16]. Among the points in  $S \cap h(p,q)$ , x is farthest from p if and only if  $q \notin D(x, p)$  and  $q \in D(x', p)$  for all  $x' \in S$  with |px'| > |px|.

Now we are ready to give our algorithm for BFIP-halfplane. Let  $p_1, \ldots, p_n$  be the sequence of input points. We first sort the *n* disks  $D(p_i, p)$  in order of non-increasing radius. Let  $D_1, \ldots, D_n$  be the resulting sequence. Thus, a disk  $D_k$  in this sequence corresponds to some disk  $D(p_i, p)$  and in general  $k \neq i$ . Let  $D_{n+1} = \emptyset$ . We build a binary tree *T* as follows. The leaves of *T* correspond to the sequence  $D_1, \ldots, D_{n+1}$ , from left to right. Each inner node *v* stores the intersection  $I_v$  of the leaf descendants of *v* (excluding  $D_{n+1}$ ). We label each node *v* with a pair  $[a_v, b_v]$  encoding the set  $S_v = \{a_v, \ldots, b_v\}$  of consecutive indices that correspond to the disks associated with the leaves of the subtree of *T* rooted at *v*. In Fig. 8 a tree with n = 13 is depicted. We build *T* in a bottom-up fashion. Each inner node has two children in the previous level, except possibly a level's rightmost node, which can have a right child in an earlier level, see the node with label [9, 13] in Fig. 8. We query *T* with the points in *S*, and the answer of a query will correspond to the index of the first disk in the sequence  $D_1, \ldots, D_{n+1}$  that does *not* contain the query point.

Unlike [9,15] we start with an empty skeleton of T, i.e., all inner nodes v are labeled by  $[a_v, b_v]$ , but all leaves and all intersections  $I_v$  are set to  $\mathbb{R}^2$ . The order in which we query becomes crucial. We go through the points  $p_1, \ldots, p_n \in S$  in order of increasing index. When we query with the point  $p_i$ , only the disks  $D(p_1, p), \ldots, D(p_{i-1}, p)$  have been inserted in T. Before querying T with  $p_i$  we update T by adding the new disk  $D_k = D(p_i, p)$  (recall that usually  $k \neq i$ ) to the intersection  $I_v$  for each node v on the path from the root to the leaf that corresponds to  $D_k$ . Querying T with  $p_i$  amounts to following a path from the root to a leaf. In each inner node v with left child  $\ell$ , the test  $p_i \in I_\ell$  is performed. If  $p_i \in I_\ell$ , the query continues with the right, otherwise with the left child of v, see Fig. 8. The leaf at the end of the query path  $\pi$  determines what our algorithm reports. Let  $D_j$  be the disk corresponding to that leaf. If  $j \leq n$ , then we report that  $p_j$  is the point farthest from p in  $\{p_1, \ldots, p_i\} \cap h(p, p_i)$ . Otherwise (i.e., if j = n + 1) we report that  $\{p_1, \ldots, p_i\} \cap h(p, p_i)$  is empty. This algorithm yields the following.

**Theorem 10.** Given a sequence S of n points and a point  $p \notin S$ , BFIP-halfplane can be solved in  $O(n \log^2 n)$  time and  $O(n \log n)$  space.

**Proof.** We first show the correctness of the above algorithm. Depending on the index of the disk  $D_j$  we consider two cases. The first case is that j = n + 1. Then  $\pi$  is the rightmost root–leaf path. Consider the left children of the nodes on  $\pi$ . The sets  $S_\ell$  that belong to these left children partition  $\{1, \ldots, n\}$ . In other words, the intersection of  $I_\ell$  over these children is  $D_1 \cap \cdots \cap D_n$ . Since  $\pi$  is the rightmost root–leaf path, the containment queries in all nodes on  $\pi$  were answered positively. Thus  $p_i$  is contained in all disks currently in T, i.e.,  $p_i \in D(p_1, p) \cap \cdots \cap D(p_i, p)$ .

This means that none of the points  $p_1, \ldots, p_i$  lies in the halfplane  $h(p, p_i)$ . Otherwise Lemma 9 would guarantee that

 $p_i \notin D(p_k, p)$  for the point  $p_k \in \{p_1, \dots, p_i\}$  farthest from p in  $h(p, p_i)$ . The second case is  $j \leqslant n$ . Again we consider the left children of the nodes on the query path  $\pi$  of  $p_i$ . The sets  $S_\ell$ partition  $\{1, \dots, j-1\}$  if we take only those left children  $\ell$  into account that do not themselves lie on  $\pi$ . Similarly to above, the intersection of  $I_\ell$  over these children is  $D_1 \cap \dots \cap D_{j-1}$ . Thus,  $p_i$  is contained in all  $D_k$  with k < j that are currently in T. On the other hand, since  $\pi$  is not the rightmost root–leaf path,  $\pi$  contains at least one node that is a left child of a node on  $\pi$ . The last such left child v is the root of the subtree whose rightmost leaf corresponds to  $D_j$ . Thus v is associated with some set  $S_v = \{i_v, \dots, j\}$ , where  $1 \leq i_v \leq j$ . Since we have already observed that  $p_i$ is contained in all  $D_k$  with k < j that are currently in T, but  $\pi$  came to v via a "no"-branch  $(p_i \notin I_v)$ , we now know that  $p_i \notin D_j$ . Let m be such that  $D_j = D(p_m, p)$ . Note that  $p_i \notin D(p_m, p)$  means that  $D(p_m, p)$  was inserted in Tbefore querying with  $p_i$ , and thus  $m \leq i$ . Since  $p_i \notin D(p_m, p)$ , and  $p_i \in D(p_r, p)$  for all  $r \leq i$  with  $|pp_r| > |pp_m|$ , Lemma 9 yields that  $p_m$  is farthest from p in  $\{p_1, \dots, p_i\} \cap h(p, p_i)$ .

The running time is as follows. Querying *T* takes  $O(\log^2 n)$  time since the height of *T* is  $O(\log n)$  and in each node of the query path the query point has to be located in the intersection  $I_v$  of some disks, which takes  $O(\log n)$  time. When we update *T* by adding a new disk  $D_j$ , we have to go from the root to the leaf that corresponds to  $D_j$ . In each node on this path we must compute  $I_v \cap D_j$  and update our data structure for  $I_v$ . This can be done in  $O(\log n)$  time per node by a procedure detailed in the proof of Lemma 4 in [16]. Thus, each update also takes  $O(\log^2 n)$  time. Now, the running time of  $O(n \log^2 n)$  is obvious. The space consumption is  $O(n \log n)$  since a) each disk contributes only to intersections stored on the path from the root to "its" leaf, and b) a disk that contributes to some intersection  $I_v$  adds at most one arc to the boundary of  $I_v$ , see Fact 2 of [16].  $\Box$ 

The definition of BFIP-halfplane and Theorem 10 can be generalized without much effort as follows. Instead of insisting that the separator of p and  $p_i$  splits  $\overline{pp_i}$  in a ratio of 1:1, any other ratio can be used as long as the split is orthogonal.

# 9. Conclusions

We have presented solutions to some very basic farthest-point problems and have shown how they can be used to solve other, more complex problems efficiently, such as simplifying polygonal paths or determining the point farthest from a query segment. Both these problems can be solved more efficiently if the solution of the underlying problem FV-halfplane can be improved. It is possible to reduce the query time to  $O(\log n)$ , e.g., by storing the farthest-point Voronoi diagrams of all  $\Theta(n^2)$  subsets of vertices that are consecutive on the given convex polygon. However, it seems hard to achieve the same improvement under the condition that space consumption and preprocessing time remain in  $O(n \log n)$ .

#### Acknowledgements

We thank Raimund Seidel for pointing us to the work of Edelsbrunner et al. [14], which helped us to reduce the preprocessing time of our data structure for FV-halfplane. We are also grateful to the anonymous referees of this paper for pointing us to an error in the proof of Theorem 3 and for simplifying the proof of Lemma 4. We thank Raghavan Dhandapani for pointing out the alternative solution for FV-halfplane with  $O(\log n)$  query time and  $O(n^3)$  preprocessing time. We finally wish to thank the DIMACS center where this research was started.
